The multi-angle instability in dense neutrino systems

R. F. Sawyer[1]

[1]*Department of Physics, University of California at Santa Barbara, Santa Barbara, California 93106*

We calculate rates of flavor exchange within clouds of neutrinos interacting with each other through the standard model coupling, assuming a conventional mass matrix. For cases in which there is an angular dependence in the relation among intensity, flavor and spectrum, we find instabilities in the evolution equations and greatly speeded-up flavor exchange. The instabilities are categorized by examining linear perturbations to simple solutions, and their effects are exhibited in complete numerical solutions to the system. The application is to the region just under the neutrino surfaces in the supernova core.

PACS numbers:

1. INTRODUCTION

There are least two astrophysical contexts in which the standard model interaction of neutrinos with neutrinos (mediated by Z exchange) could play a important role:

1). In the supernova process, either in the region just under the neutrinosurface (i.e. the point of last scattering, on the average), or in the regions just outside of this region. The energy distributions of the various species of neutrino in this region are important to the dynamics of the explosion, to R process nucleosynthesis downstream, and to the observed neutrino pulse on earth, should it ever be observed again. These energy distributions may be affected greatly by coherent neutrino-neutrino interactions, even though the effects of ordinary incoherent $\nu-\nu$ scattering are small. There has been much recent work on the combined effects of ν-ν interactions and oscillations in the region outside the neutrino surfaces for neutrinos of different flavors[1]-[7].

2). In models of the early universe before nucleosynthesis (but after leptogenesis, etc. and well before ν decoupling) in which there are substantial neutrino chemical potentials, that is to say, neutrino anti-neutrino imbalance at much greater level than the electron- positron imbalance. If flavors are out of equilibrium as well, then $\nu-\nu$ interactions become important. When sterile neutrinos are added, these scenarios become arbitrarily complex. They can easily change the parameters that determine the He abundance, so that a part of the effort expended on their behalf has been to avoid upsetting the good fits of the standard theory. The models can be arranged to produce models of sterile neutrino dark matter in the mass region at least several KeV, coupled with a mixing parameter small enough not to conflict with cosmic x-ray backgrounds [8]-[10].

The present work operates in the context of the supernova problem, although there could well be applications to the area b), above, as well. Here we consider some effects below the neutrino surface, or, more accurately, in the transitional region at about the depth of the average last scattering for $\nu_{\{\mu,\tau\}}$ and $\bar\nu_{\{\mu,\tau\}}$, and below the depth of the average last scattering for ν_e and $\bar\nu_e$. This follows up on previous work [11], [12] in the same region, demonstrating the possibility of flavor instabilities causing rapid mixing of the angular distributions and energy spectra. In these instabilities, which depend only on forward ν processes, flavor is traded between momentum states with no change in the momentum states. The instabilities arise when neutrino momentum distributions are anisotropic. The examples worked out in refs. [5],[6] dealing with a region outside of the neutrino-surfaces have at their core the type of instability as that described in [11], [12], which we characterize as the "multi-angle instability."

The present work has three purposes:

a) To provide a better basis for understanding these instabilities, described in the above references simply in terms of the plots produced in simulations. In the present paper we carry out standard linearized stability analysis of the underlying nonlinear systems.

b) To do a more realistic analysis than was done in ref. [11] of flavor-scrambling effects in the region just under the neutrino surfaces. For example, in the current work we show results for a case with 14 bins of ν momentum space, as compared to 2 bins in ref. [11]

c) To point out a second category of possible instability, potentially more potent than the one underlying the work mentioned above. A feature of the results is that small fluctuations of initial distributions away from symmetrical cases can have a catalyzing effect, inducing complete flavor transfers between up-moving and down-moving states.

Our effects evolve over small distances in homogeneous matter, in contrast to MSW resonance flavor trading, which depends on passage through more extended regions with variable electron density. They also act to mix up neutrino and anti-neutrino flavors simultaneously, in contrast to resonant phenomena, which act on one or the other.

The medium in the region of the neutrinosurfaces has density of a few times 10^{11} g c^{-3} at a temperature $T = 5-7$ MeV. We shall consider neutrino mixing of two species, ν_e and (following the notation of other authors) ν_x, where ν_x is some mixture of ν_μ ν_τ. There are a number of time scales that we can define in this region:

1. A "very fast" time scale $(G_F n_\nu)^{-1}$, where n_ν is the neutrino number density $n_e \sim T^3$. In our domain this time is of order 10^{-3}cm. in units in which $c = 1$.

2. The vacuum oscillation time, of order 10^7 cm. in our region, for $\delta m^2 = .8 \times 10^{-4}(\mathrm{eV})^2$. All of the rates of change for interesting quantities that we calculate in the present paper will be much faster than this rate.

3. A "fast" rate that is the geometric mean of the above two rates. The fact that properties of ν systems can change at this rate was noted by Kostelecky and Samuel [13] [14] in their work on self-maintained coherent oscillations in dense isotropic neutrino gases. More recent exploration of this topic can be found in refs. [15] and [16]. This basic rate recurs in the multi-angle flavor instabilities found in refs. [5],[6],[11].

4. The rate for scattering from neutrons and protons in the medium $\sim G_F^2 T^3$ about ten times as fast as the vacuum oscillation rate in the domain of interest.

The equations for flavor density matrices needed to derive our principal results are standard by now [17]. But in order to explain some caveats in a later section and to set the groundwork for future work we shall briefly rederive the standard equations.

We consider a system of neutrinos interacting with each other through the Z mediated neutral current couplings, and with electrons and positrons in the medium, through the W and Z mediated couplings. Interactions of ν's with nucleons in the medium are irrelevant, as far as the main developments are concerned, since they are independent of ν flavor. We also include ordinary neutrino oscillations. The effects of ordinary incoherent scattering by nucleons and electrons in the medium can be neglected over the time scales that we consider.

We define $a_e(\mathbf{p})$ and $a_x(\mathbf{p})$, as the respective annihilation operators for a ν_e and ν_x of momentum $\mathbf{p}$, with corresponding definitions for the operators that annihilate $\bar{\nu}$'s. We introduce the density operators,

$$\begin{aligned} \rho_{i,j}(\mathbf{p}) &= a_i(\mathbf{p})^\dagger\, a_j(\mathbf{p}) \\ \bar{\rho}_{i,j}(\mathbf{p}) &= \bar{a}_j(\mathbf{p})^\dagger\, \bar{a}_i(\mathbf{p})\,, \end{aligned} \tag{1}$$

where i and j take the values e or x. Note the transposition of indices in the definition of the antiparticle density operator; the leads to neater formulae below.

The reason that ν-ν interactions can change flavor-spectrum correlations over a very short time scale is that in a pure forward encounter between two neutrinos the neutrinos can swap flavors, thus engendering coherent (because of forward) effects that are more than phases in their wave-functions (because of flavor dependence). We start therefore by isolating from the Z exchange coupling all of the terms with no momentum exchange, that is, the terms that connect a pair of ν's with momenta $\mathbf{p},\mathbf{q}$ to a pair with momentum $\mathbf{p},\mathbf{q}$; only the flavors being changed. We shall refer to this as the "forward" neutrino-neutrino interaction, $H_{\nu,\nu}$,

$$\begin{aligned} H_{\nu\nu}(\rho) = \tfrac{\sqrt{2}G_F}{V} \textstyle\sum_{\mathbf{p},\mathbf{q}}\ \sum_{\{i,j\}=e,x} &[1-\cos(\theta_{\mathbf{p},\mathbf{q}})] \\ \times \Big[\Big(\rho_{i,j}(\mathbf{p}) - \bar{\rho}_{i,j}(\mathbf{p})\Big)&\Big(\rho_{j,i}(\mathbf{q}) - \bar{\rho}_{j,i}(\mathbf{q})\Big) \\ + \Big(\rho_{i,i}(\mathbf{p}) - \bar{\rho}_{i,i}(\mathbf{p})\Big)&\Big(\rho_{j,j}(\mathbf{q}) - \bar{\rho}_{j,j}(\mathbf{q})\Big)\Big]\,, \end{aligned} \tag{2}$$

where V is the volume.

The oscillation (or mass-matrix) term H_{osc} is taken to be of the form,

$$\begin{aligned} &H_{\mathrm{osc}}(\rho) = \\ &\textstyle\sum_{\mathbf{p}} \Big[|2\mathbf{p}|^{-1}\eta[\rho_{e,x}(\mathbf{p}) + \rho_{x,e}(\mathbf{p}) + \bar{\rho}_{e,x}(\mathbf{p}) + \bar{\rho}_{x,e}(\mathbf{p})] \\ &+|2\mathbf{p}|^{-1}\xi[\rho_{e,e}(\mathbf{p}) - \rho_{x,x}(\mathbf{p}) + \bar{\rho}_{e,e}(\mathbf{p}) - \bar{\rho}_{x,x}(\mathbf{p})] \\ &+G_F n_e[\rho_{e,e}(\mathbf{p}) - \rho_{x,x}(\mathbf{p}) - \bar{\rho}_{e,e}(\mathbf{p}) + \bar{\rho}_{x,x}(\mathbf{p})]\Big]\,, \end{aligned} \tag{3}$$

where the parameters ξ, η determine the standard vacuum neutrino mass parameters according to $\delta m^2 = (\xi^2 + \eta^2)$, $\tan(\theta) = \eta/\xi$, and the third line in (3) comes from the standard model neutrino electron interaction.

In the main part of what follows, we discuss the time evolution of a neutrino system under the influence of the Hamiltonian H_1, where,

$$H_1(\rho) = H_{\nu\nu}(\rho) + H_{\mathrm{osc}}(\rho)\,. \tag{4}$$

Since $H_1(\rho)$ in (4) leaves the momenta of the individual neutrinos unchanged, the kinetic energy term (in the absence of neutrino mass) is irrelevent to evolution under the influence of $H_1(\rho)$.

The commutation rules of the density operators are

$$[\rho_{i,j}(\mathbf{p}), \rho_{k,l}(\mathbf{p}')] = [\delta_{i,l}\rho_{k,j}(\mathbf{p}) - \delta_{j,k}\rho_{i,l}(\mathbf{p})]\delta_{\mathbf{p},\mathbf{p}'}\,,$$

$$[\bar{\rho}_{i,j}(\mathbf{p}), \bar{\rho}_{k,l}(\mathbf{p}')] = [-\delta_{i,l}\bar{\rho}_{k,j}(\mathbf{p}) + \delta_{j,k}\bar{\rho}_{i,l}(\mathbf{p})]\delta_{\mathbf{p},\mathbf{p}'}\,. \tag{5}$$

With this apparatus the usual equations for the density functions are of the Heisenberg form,

$$i\frac{d}{dt}\rho_{i,j}(\mathbf{p}) = [\rho_{i,j}(\mathbf{p}), H]\,. \tag{6}$$

We obtain,

$$\begin{aligned} \tfrac{d}{dt}\rho_{i,j}(\mathbf{p}) = \tfrac{-\sqrt{2}G_F}{V} \textstyle\sum_{\mathbf{q}}\sum_k \Big[&\rho_{i,k}(\mathbf{p})[\rho_{k,j}(\mathbf{q}) - \bar{\rho}_{k,j}(\mathbf{q})] \\ -\rho_{j,k}(\mathbf{p})[\rho_{i,k}(\mathbf{q}) - \bar{\rho}_{i,k}(\mathbf{q})]\Big]&[1-\cos(\theta_{\mathbf{p},\mathbf{q}})] \\ &+|\mathbf{p}|^{-1}[\Lambda, \rho(\mathbf{p})]_{i,j}\,, \end{aligned} \tag{7}$$

and,

$$\begin{aligned} \tfrac{d}{dt}\bar{\rho}_{i,j}(\mathbf{p}) = \tfrac{-\sqrt{2}G_F}{V} \textstyle\sum_{\mathbf{q}}\sum_k \Big[&\bar{\rho}_{i,k}(\mathbf{p})[\rho_{k,j}(\mathbf{q}) - \bar{\rho}_{k,j}(\mathbf{q})] \\ -\bar{\rho}_{j,k}(\mathbf{p})[\rho_{i,k}(\mathbf{q}) - \bar{\rho}_{i,k}(\mathbf{q})]\Big]&[1-\cos(\theta_{\mathbf{p},\mathbf{q}})] \\ &+|\mathbf{p}|^{-1}[\Lambda, \bar{\rho}(\mathbf{p})]_{i,j}\,. \end{aligned} \tag{8}$$

For brevity we expressed the part coming from the commutator with $H_{\rm osc}$ in (3) terms of a conventional generator $\Lambda(\lambda,\xi)$, a 2×2 matrix in the flavor space.

2. MEAN FIELD EQUATIONS

In this paper we concentrate on a "mean-field" limit, in which the operators (in the occupation number space), $\rho_{i,j}$, are replaced by their expectation values in the medium, $<\rho_{i,j}>$, *after* the commutators (in the occupation number space) have been performed to give the evolution equations (7),(8).

This mean field assumption can be stated as

$$\langle\rho_{i,j}(p)\rho_{k,l}(p')\rangle = \langle\rho_{i,j}(p)\rangle\langle\rho_{k,l}(p')\rangle\,. \tag{9}$$

In this case we can suppress the indices $<\rho_{i,j}>$ and write the evolution equations (7) and (8) as matrix equations in the flavor indices, generated in canonical fashion by effective mode by mode Hamiltonians for the matrices $\rho(p)$,

$$\begin{aligned} H_{eff}(\mathbf{p}) = \tfrac{\sqrt{2}G_F}{V} \textstyle\sum_{\mathbf{q}}[\rho(\mathbf{q})-\bar\rho(\mathbf{q})][1-\cos(\theta_{\mathbf{p},\mathbf{q}})] \\ +|\mathbf{p}|^{-1}\Lambda\,. \end{aligned} \tag{10}$$

We emphasize that the formulation based on (10) depends totally on the mean field assumption. Although it probably gives the correct answers in the problems that we address, we shall return to discuss possible corrections to the mean-field approximation. This discussion must be based on (2) rather than on (10).

For computational purposes we introduce collective variables for neutrinos by subdividing the momentum space into some small number $N_{\rm B}$ of regions $\{\alpha\}$ which we designate as beams. For convenience we will do the subdivision so that there are the same number of neutrinos + antineutrinos, N_ν, in each beam α,

$$N_\nu = \sum_i\sum_{\mathbf{p}\subset\{\alpha\}}[\rho_{i,i}(\mathbf{p})+\bar\rho_{i,i}(\mathbf{p})] = n_\nu V/N_{\rm B}\,. \tag{11}$$

Then we define density matrices for the individual beams,

$$\rho^{(\alpha)}_{i,j} = N_\nu^{-1}\sum_{\mathbf{p}\subset\{\alpha\}}\rho_{i,j}(\mathbf{p})\,, \tag{12}$$

and

$$\bar\rho^{(\alpha)}_{i,j} = N_\nu^{-1}\sum_{\mathbf{p}\subset\{\alpha\}}\bar\rho_{i,j}(\mathbf{p})\,, \tag{13}$$

so that in each beam, α, we have,

$$\sum_j[\rho^{(\alpha)}_{j,j}+\bar\rho^{(\alpha)}_{j,j}] = N_B^{-1}\,. \tag{14}$$

For calculations we need only two operators in each beam for particles and two for antiparticles. We define,

$$\begin{aligned} r_\alpha = \rho^{(\alpha)}_{e,x}\quad,\bar r_\alpha = \bar\rho^{(\alpha)}_{e,x}, \\ z_\alpha = \rho^{(\alpha)}_{e,e}-\rho^{(\alpha)}_{x,x}\quad,\quad \bar z_\alpha = \bar\rho^{(\alpha)}_{e,e}-\bar\rho^{(\alpha)}_{x,x}\,. \end{aligned} \tag{15}$$

In the two flavor case it has become conventional to write the evolution equations for matrices that are hermitean 3-vectors in the internal flavor space. But it is computationally more efficient to use, for each value of α, non-hermitian r_α's, introduced above, rather than the two hermitian components.

The effective Hamiltonian is now,

$$\begin{aligned} H = \tfrac{\sqrt{2}G_F N_\nu n_\nu}{N_B}\textstyle\sum_{\alpha,\beta}\Big[2(r_\alpha-\bar r_\alpha)^\dagger(r_\beta-\bar r_\beta) \\ +(z_\alpha-\bar z_\alpha)(z_\beta-\bar z_\beta)\Big]\times[1-\cos\theta_{\alpha,\beta}] \\ +N_\nu\textstyle\sum_\alpha\Big[|\mathbf{p}_\alpha|^{-1}\lambda(r_\alpha+r^\dagger_\alpha+\bar r_\alpha+\bar r^\dagger_\alpha)+|\mathbf{p}_\alpha|^{-1}\xi(z_\alpha+\bar z_\alpha) \\ +G_F n_\nu(z_\alpha-\bar z_\alpha)\Big]\,. \end{aligned} \tag{16}$$

We have here dropped in (2) the terms that involve only $\sum_i\rho_{i,i}(p)$ and $\sum_i\bar\rho_{i,i}(p)$, since these quantities are conserved under the present dynamics [1]

From (5)and (15) the commutation rules of our dimensionless variables are

$$\begin{aligned} [r_\alpha,r^\dagger_\beta] = N_\nu^{-1}z_\alpha\,\delta_{\alpha,\beta}\quad,\quad [r_\alpha,z_\beta] = 2N_\nu^{-1}r_\alpha\,\delta_{\alpha,\beta} \\ [\bar r_\alpha,\bar r^\dagger_\beta] = -N_\nu^{-1}\bar z_\alpha\,\delta_{\alpha,\beta}\quad,\quad [\bar r_\alpha,\bar z_\beta] = -2N_\nu^{-1}r_\alpha\,\delta_{\alpha,\beta}\,. \end{aligned} \tag{17}$$

The equations for time evolution are given for the flavor changing operators by,

$$\begin{aligned} i\tfrac{d}{dt}r_\alpha = \tfrac{\sqrt{2}G_F n_\nu}{N_{\rm reg}}\textstyle\sum_\beta\Big[z_\alpha(r_\beta-\bar r_\beta)-r_\alpha(z_\beta-\bar z_\beta)\Big] \\ \times[1-\cos\theta_{\alpha,\beta}]+(\eta z_\alpha-\xi r_\alpha)/|\mathbf{p}_\alpha|+G_F n_e r_\alpha\,, \\ \\ i\tfrac{d}{dt}\bar r_\alpha = -\tfrac{\sqrt{2}G_F n_\nu}{N_{\rm reg}}\textstyle\sum_\beta\Big[\bar z_\alpha(\bar r_\beta-r_\beta)-\bar r_\alpha(\bar z_\beta-z_\beta)\Big] \\ \times[1-\cos\theta_{\alpha,\beta}]-(\eta\bar z_\alpha-\xi\bar r_\alpha)/|\mathbf{p}_\alpha|+G_F n_e\bar r_\alpha\,, \end{aligned} \tag{18}$$

and for the flavor conserving operators by,

$$\begin{aligned} i\tfrac{d}{dt}z_\alpha = -\tfrac{\sqrt{2}G_F n_\nu}{N_B}\textstyle\sum_\beta\Big[r^*_\alpha(\bar r_\beta-r_\beta)-r_\alpha(\bar r^*_\beta-r^*_\beta)\Big] \\ [1-\cos\theta_{\alpha,\beta}]+2\eta(r_\alpha-r^*_\alpha)/|\mathbf{p}_\alpha|\,, \\ \\ i\tfrac{d}{dt}\bar z_\alpha = \tfrac{\sqrt{2}G_F n_\nu}{N_B}\textstyle\sum_\beta\Big[\bar r^*_\alpha(r_\beta-\bar r_\beta)-\bar r_\alpha(r^*_\beta-\bar r^*_\beta)\Big] \\ [1-\cos\theta_{\alpha,\beta}]-2\eta(\bar r_\alpha-\bar r^*_\alpha)/|\mathbf{p}_\alpha|\,. \end{aligned} \tag{19}$$

---

[1] These terms would enter the dynamics if, for example, we were including mixing with sterile neutrinos.

Note that in the equations (18), (19), once we take the mean-field limit, the Hermitian adjoints in the original operator expressions turn into simple complex conjugates of the functions.

We shall use (18), (19) to determine the evolution of the system starting from a flavor-diagonal initial state at $t = 0$, that is, from $r_\alpha(0) = 0$, $\bar{r}_\alpha(0) = 0$. Consider first the system with the parameter $\eta = 0$, and the initial values $r_\alpha = 0$, $\bar{r}_\alpha = 0$. Then the solution has values of z_α, $\bar{z}_\alpha$, that are constant in time, with vanishing r_α, $\bar{r}_\alpha$. We examine the stability by linearizing around this solution. We note that the linear perturbations of the z's do not enter (18) at all, so that we have linear equations for perturbations δr_α, $\bar{\delta} r_\alpha$. Grouping these perturbations into a single column vector $\delta\Omega_{\alpha,i}$ where $i = 1$ picks out δr_α, and $i = 2$ picks out $\bar{\delta} r_\alpha$, we write the equations in matrix form as,

$$i\frac{d}{dt}\,\delta\Omega = M\,\delta\Omega\,, \tag{20}$$

where M is a $2N_{\rm B}$ dimensional square matrix with elements $M_{\alpha,i;\beta,j}$ that we read out from (18) as,

$$\begin{aligned}
M_{\alpha,1;\beta,1} &= \sqrt{2}G_F n_\nu N_B^{-1}\Big[z_\alpha[1-\cos\theta_{\alpha,\beta}] \\
&-\delta_{\alpha,\beta}\sum_\gamma (z_\gamma - \bar{z}_\gamma)[1-\cos\theta_{\alpha,\gamma}]\Big] - \xi|\mathbf{p}_\alpha|^{-1}\delta_{\alpha,\beta}\ , \\
M_{\alpha,1;\beta,2} &= -\sqrt{2}G_F n_\nu N_B^{-1}\, z_\alpha[1-\cos\theta_{\alpha,\beta}]\,, \\
M_{\alpha,2;\beta,1} &= \sqrt{2}G_F n_\nu N_B^{-1}\, \bar{z}_\alpha[1-\cos\theta_{\alpha,\beta}]\,, \\
M_{\alpha,1;\beta,1} &= -\sqrt{2}G_F n_\nu N_B^{-1}\Big[-\bar{z}_\alpha[1-\cos\theta_{\alpha,\beta}] \\
&-\delta_{\alpha,\beta}\sum_\gamma (z_\gamma - \bar{z}_\gamma)[1-\cos\theta_{\alpha,\gamma}]\Big] + \xi|\mathbf{p}_\alpha|^{-1}\,\delta_{\alpha,\beta}\ .
\end{aligned} \tag{21}$$

The flavor-diagonal initial conditions determine the $2\,N_{\rm B}$ parameters z_α, $\bar{z}_\alpha$ in (21). The instabilities that are the focus of the present paper all arise from a complex eigenvalue, λ_i of M. There are two categories of instabilities that can arise:

a) Cases in which there is a complex eigenvalue even when $\xi = 0$. The growth rate of the mode can be some appreciable fraction of $G_F n_e$, the "very fast" rate mentioned in the introduction. This situation only arises when the angular distributions in the initial state are somewhat complex .

b) Cases in which the eigenvalues are real when $\xi = 0$ but for the case of non-vanishing ξ are complex with imaginary part of order $(G_F \xi n_\nu/|\mathbf{p}|)^{1/2}$, for small ξ. This is the "fast rate" mentioned in the introduction, still much faster than the ordinary collision frequency in our region of interest.

3. SIX BEAM EXAMPLE

We have done a number of simulations with different distributions in angle and flavor. Simulations including bins of different energies have been done as well, but it turns out that including an energy spectrum in the dynamics makes little difference to the results, although energy enters in the factor $|\mathbf{p}|^{-1}$ in the oscillation rate. This is basically the synchronization phenomenon discussed in refs [13]. Of course, energy enters in a bookkeeping way, since the main point will be the equalization of the ν_x spectrum and the ν_e spectrum through flavor trading.

Since a flavor independent distribution $\rho_{i,j} = \delta_{i,j}$ is completely irrelevent in these equations, we can subtract a flavor independent $n_{\rm FI}$ part, replacing the multiplying n_ν in (18) and (19) by $n_{\rm eff} = (n_\nu - n_{\rm FI})$, and giving a residual distribution that is all (or nearly all) ν_x's going up and ν_e's going down. We begin with one of the simpler cases for which we have carried out numerical solutions of the evolution equations.

The physics is that in a critical region the ν_x, $\bar{\nu}_x$ have an outward bias in their momentum distributions while the ν_e, $\bar{\nu}_e$ are more istropically distributed. Also there is some excess of ν_e overall , coming from the tail of the deleptonization pulse. This excess dies off rather fast compared to the time scale of total neutrino energy loss from the star. The ν_x, $\bar{\nu}_x$ also have a harder energy spectrum; as noted above, this latter fact is fairly unimportant as far as the mechanics of flavor exchanges is concerned, but of course it is central to the conclusions being interesting.

For the simulation, take six beams, $N_{\rm grp} = 6$, oriented in the $\pm\hat{x}\,, \pm\hat{y}\,, \pm\hat{z}$ directions in ordinary space, which we label as the $\pm 1\ \pm 2\,, \pm 3$ directions.

We take the following values for the functions in (18), (19) at $t = 0$:

$$\begin{aligned}
z_3(0) = -1\ ,&\ \ \bar{z}_3(0) = -1\ , \\
z_{\pm 1}(0) = g\ ,&\ \ \bar{z}_{\pm 1}(0) = 0\ , \\
z_{\pm 2}(0) = g\ ,&\ \ \bar{z}_{\pm 2}(0) = 0\ , \\
z_{-3}(0) = 1 + 2g\ ,&\ \ \bar{z}_{-3}(0) = 1\ .
\end{aligned} \tag{22}$$

Here, the $\hat{3}$ direction is up (i.e., outward) and the choice $z_3 n_{\rm eff} = \rho^{(3)}_{e,e} - \rho^{(3)}_{x,x} = -n_{\rm eff}$ for the density function for the upward flux indicates an excess of ν_x's over ν_e's. Likewise the part with unity in the down direction reflects the excess of $\nu_e\,, \bar{\nu}_e$ in the downward direction. A distribution that is independent of particle flavor is sterile and can be subtracted. We categorize the remainder as:

1) In the up direction, all $\nu_x\,, \bar{\nu}_x$'s.

2) In the transverse directions, equal numbers of $\nu_x\,, \bar{\nu}_x$, $\bar{\nu}_e$, but with an excess of ν_e, measured by the parameter g.

3) In the downward direction, all ν_e, $\bar{\nu}_e$, with a greater excess of ν_e.

We introduce a dimensionless parameter R to measure the ratio of the vacuum oscillation rate to the "very fast" neutral current rate,

$$R = (\delta m^2)(G_F n_{(0)}|\mathbf{p}|)^{-1} \sim 10^{-9} \tag{23}$$

where the estimate is for the conditions that we describe above, using the solar neutrino value $\delta m^2 \approx 10^{-4}$. In our numerical studies, we have looked at the region $10^{-8} < R < 10^{-2}$, with fixed, physical $\sin^2(2\theta_{\rm vac}) = .86$.

In our first example we choose ξ to be positive, which corresponds to the "inverted hierarchy". We look at the eigenvalues of the matrix M of (21) in the case $g = .2$, which corresponds to a ν_e surplus of roughly $(\nu_e - \bar{\nu}_e)/\bar{\nu}_e$ of 10% , obtaining, among the twelve eigenvalues, λ_i one complex conjugate pair with imaginary part,

$$\mathrm{Im}[\lambda] = .66[G_F\, R]^{1/2}\,, \tag{24}$$

where the exponent 1/2 is essentially exact over a region in which R changes by over six orders of magnitude.

Next we calculate the evolution of the system by solving the twelve equations (18), (19) with the initial conditions given by (22), for a range of parameters g (representing ν_e excess), ξ, with λ determined by keeping the value $\sin^2(2\theta) =$ fixed.

In the example shown, we took an electron density corresponding to matter with a density of 5×10^{11}gc^{-3}, and electron fraction $Y_e = .4$. We take a neutrino density n_ν for each species given by a thermal density at a temperature of 7 MeV; and for definiteness $n_{\rm eff} = .2 n_\nu$, and $g = .2$ as above.

Again we have calculated the development as a function of R over the range $10^{-1} > R > 10^{-7}$. Results are shown in fig. 1 for the case $R = 10^{-5}$. For our range of R we find that the first peak corresponding to total flavor takeover comes at a mixing time $t_{\rm mix}$,

$$t_{\rm mix}^{-1} = G_F n_{\rm eff} [R]^{.56}\,, \tag{25}$$

where the fit is (within our precision) *exact* over six decades as we change R. We have no insight into this law, except insofar as we anticipated something close to $R^{.5}$ dependence, based on the eigenvalue dependence noted above. Of course we would not have anticipated an exact $R^{.5}$ law, since the system is completely into a nonlinear domain by the time of maximal mixing.

Now extrapolating to the value $R = 10^{-9}$ appropriate to neutrinos with average number density corresponding to temperature $T = 7$ MeV, and energies of order 20 MeV we find that the first turnover of flavor occurs in a distance ~ 30 cm.

Keeping the beam configuration and the initial assignments fixed as above we have varied the parameters in the solutions to see if there are qualitative sensitivities:

a. Changing the all-over neutrino density, n_ν ,(i.e. the temperature) or the ratio, $n_{\rm eff}/n_\nu$, (i.e. the scale of the initial asymmetry) is unimportant. It is true that with a smaller asymmetry the flavor exchange will be slower, but for the case of our parameter region the exchange will still be fast measured in terms of other time scales in the problem. In particular the turnover region is small compared to the (rather idealized) distance between a ν_e-surface and a ν_x-surface (of last scatterings).

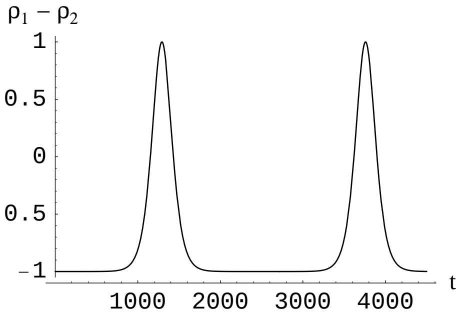

FIG. 1: Plot of the changing ν_e, ν_x asymmetry in the upward hemisphere, $\rho_1 - \rho_2$, for the case $R = 10^{-4}$ and inverted hierarchy, where $\langle\rho_{\{1,2\}}\rangle$ are the respective densities of the two flavors as measured in the units $n_{\rm eff}$. The initial value, $\rho_1 - \rho_2 = -1$ indicates total occupancy of our subset of states with ν_x's. The unit of time is the inverse of the fast rate $G_F n_{\rm eff}$.

b. Changing the electron density is also not at all interesting; a change by a factor of 2 typically makes a change of no more than 10% in the position of the tipping point.

c. For the case of the "normal" hierarchy we get instability only for very small ν_e excess. This observation agrees completely with the findings of ref. [6]. We would map out the region of instability in more detail, except that the results of the next section, where the initial angular distributions are taken to be more complex, provide a much likelier mechanism for rapid mixing in case of the normal hierarchy.

d. Ordinary scattering is very unlikely in the turnover times that correspond to fig. 1. But we could think of including it to see where the effect of damping by scattering leaves the distributions after many, many oscillations of the type shown in fig. 1. Note that in the data shown the time-averaged occupancies retain most of the initial asymmetry, in spite of the spikes to reversed occupancy. Taking damping from scattering, following the prescriptions of McKellar and Thomson [18] (where, in the monoenergetic idealization the effects are just a damping term in equations for the off-diagonal parts of the density matrix), we indeed find near zero asymmetry and little residual oscillation after only one or two scattering times. We could not do these calculations using the physical values of the parameters, however, because this would have required hundreds of the oscillations of which two are shown in fig. 1. However in the next section we find that with more chaotic initial conditions we get complete mixing in the time average at shorter times, and without scattering.

4. MORE COMPLEXITY

We move to better coverage, with 14 rays replacing the 6 in the simulations of the preceding section. To the earlier configuration of rays we add the eight beams that make an angle of $\pi/4$ with the z axis and are positioned in the x, z or y, z planes. For the four of these beams in the upward hemisphere, we assign common initial values z_u,$\bar{z}_u$ that interpolate between the upward and horizontal beams of (22),

$$z_u(0) = -.5 + \delta/2 \ , \ \bar{z}_u(0) = -1 \ . \tag{26}$$

Similarly for the four new beams in the downward hemisphere, with common initial values z_d, $\bar{z}_d$, where we interpolate between the completely inward ray in (22) and the horizontal rays to get the common values,

$$z_d(0) = .5 + 3\delta/2 \ , \ \bar{z}_d(0) = -.5 \ . \tag{27}$$

We easily confirm the qualitative conclusions of the last system, in this somewhat finer grained simulation of the same physics. That is to say, we again find an instability with growth rate proportional to the geometric mean between the "very fast" rate $G_F\, n_\nu$ and the ordinary vacuum oscillation parameter, with nearly the same coefficient and limitations of parameter domains, and a detailed plot recapitulating fig. 1.

Next we put independent random variations in the 28 initial values. Unfortunately, a whole landscape of new possibilities arise. To quantify this in an example we return to the linearized instability condition based on the eigenvalues of M of (21) in our bigger space, but now adding independent variations $\Delta z_i(0), \Delta\bar{z}_i(0)$, distributed randomly on the interval $\{-.05, .05\}$. We begin by turning off the neutrino mass, $\delta m^2 = 0$. For the case of the electron excess parameter, $\delta = .1$, we find that somewhat over 50 % of the time there is at least one complex eigenvalue of M. Note that the hierarchy is not an issue at this point since $\delta m^2 = 0$. The ν_e excess still can matter; when we increase the excess ν_e parameter to $\delta = .2$ the probability of a complex eigenvalue decreases to around 25%.

When we proceed to calculate the evolution from the full equations (18), (19), we find that in almost every case with a complex eigenvalue there is rapid mixing of flavors among the rays that go upwards and the rays that go downwards, but it is more irregular that the behavior shown in fig. 1. We show a typical example in fig. 2 for the case $R = 10^{-4}$, where results for both signs of δm^2 are plotted.

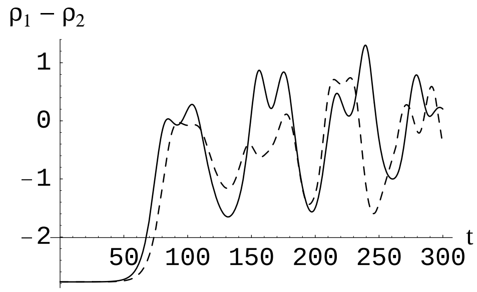

FIG. 2: For a 14 beam case with the initial conditions as specified in (22), (26),(27), with small (10%) initial irregularities introduced so that there is a growing mode in the linearized equations even in the absence of neutrino mass terms. Plot of the changing ν_e, ν_x asymmetry in the upward hemisphere, $\rho_1 - \rho_2$ where $\langle\rho_{\{1,2\}}\rangle$ are the respective densities of the two flavors as measured in the units $n_{\rm eff}$. The initial value -1 indicates total occupancy of our subset of states with ν_x's. The unit of time is the inverse of the fast rate $G_F n_{\rm eff}$.

We note that the differences between the normal and inverted sign are minor. In fig. 3, we show a calculation with the same initial conditions but for the value $R = 10^{-5}$.

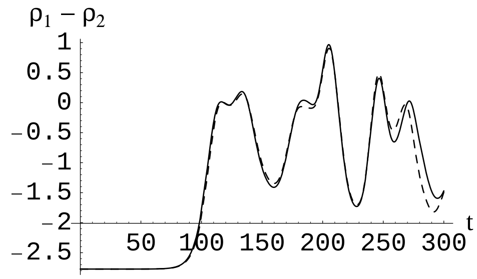

FIG. 3: The same conditions as shown in fig. 2 but with a neutrino mass parameter $R = 10^{-5}$, instead of 10^{-4}, showing almost the same behavior for the normal and inverted hierarchy cases.

For even smaller values of R all visible differences between normal and inverted hierarchies disappear. For the range of values $10^{-6} < R < 10^{-2}$ we find that (25) can be replaced by,

$$t_{\rm mix}^{-1} = G_F n_{\rm eff} [R]^{.18} \, , \tag{28}$$

although the fit is no longer perfect. In any case the flavor mixing is even faster that that estimated in the last section, and it is much more thorough.

As an example we take initial conditions defined by beginning with neutrino number densities characteristic of equilibrium at $T = 7$ MeV, then shift 20% of the down-moving ν_x, $\bar{\nu}_x$ to up-moving states, and do the reverse for the ν_e, $\bar{\nu}_e$ distributions. In this case we find total mixing in the time corresponding to .2 cm. of neutrino path. In general it is clearly not the detailed calculation of evolution, as shown in fig. 2, that is important, but rather the simple linearized analysis that detects a growing mode.

The latter depends on the scale of the anisotropies only through the fact that the parameter g of (22) measures the amount of ν_e relative to the up-down asymmetric part of the main $\nu, \bar{\nu}$ distributions. Thus scaled-down anisotropies in the presence of a big ν_e excess lead to a smaller chance of instability, according to our earlier analysis. [2] We conclude, however, that if the angular distributions are anywhere nearly as irregular as the usual quantities displayed in the results of simulations of the core physics (e.g. Y_e), then there should be many opportunities for instability.

5. EXAMINATION OF THE THE MEAN FIELD APPROXIMATION.

Although we don't find it obvious from the literature, we believe that getting from the underlying field theory to the evolution equations for the density matrices involves two separate steps that need to be examined separately.

1.)Replacing the Hamiltonian by the "forward" Hamiltonian of (2).

2.)Making the "mean field" assumption (9).

The first question is: why do we believe that it is legitimate to ignore almost all of the terms in the neutrino-neutrino interaction that correspond (in Born approx.) to scattering at a finite angle? Clearly it is because we are looking for index of refraction effects, in a sense of order G_F, rather than scattering, where cross-sections are of order G_F^2.

This oversimplifies; the domains do overlap. For example, in considering neutrinos passing through an inhomogenious sea of electrons, density fluctuations on a scale much greater than the than the ν wavelength, it is correct to scatter from a space varying index of refraction (coming from the "forward" interaction Hamiltonian) in place of explicitly adding up waves coming from the small angle scattering on each electron. But are we sure that when neutrinos are the target and are themselves subject to flavor manipulation from the beam, the index of refraction matrix from forward processes embodies all of the physics? Or could small angle (rather than forward) terms enter the analysis in some nastier way?

That said, and accepting the applicability of the "forward" Hamiltonian, over time periods for which scattering is small, we can ask about the validity of the mean field approximation. The essence of the question is captured using a truncated form of the neutral current interaction. We return to the effective Hamiltonian (16) and discard the oscillation terms and all antiparticle operators, and also insert a parameter η multiplying the term in which the operators do not change the flavor ,

$$H = G \sum_{\alpha,\beta} \Big[2 r_\alpha^\dagger r_\beta + \eta z_\alpha z_\beta \Big] [1 - \cos\theta_{\alpha,\beta}] \,. \tag{29}$$

We take only an up beam A and a down beam B , and change to the notation appropriate to a system of N spin 1/2 particles in group A and N in group B,

$$z_1 = \sum_{i \subset A} \sigma_3^i \quad , \quad z_2 = \sum_{i \subset B} \sigma_3^i \quad ,$$
$$r_1 = \sum_{i \subset A} \sigma_{(+)}^i \quad , \quad r_2 = \sum_{i \subset B} \sigma_{(+)}^i \ . \tag{30}$$

The (mean field) evolution equations are,

$$i\frac{d}{dt} r_1 = G(z_1 r_2 - \eta r_1 z_2)$$
$$i\frac{d}{dt} r_2 = G(z_2 r_1 - \eta r_2 z_1) \,, \tag{31}$$

and

$$i\frac{d}{dt} z_1 = G(r_1 r_2^* - r_1^* r_2)$$
$$i\frac{d}{dt} z_2 = G(r_2 r_1^* - r_2^* r_1) \,. \tag{32}$$

We take initial $z_1(0) = N$, $r_1(0) = 0$(spins up) ; $z_2(0) = -N$; $r_2(0) = 0$ (spins down). The eigenvalues that determine stability in the linearized system are easily read off from (31), $\lambda = \pm GN\sqrt{\eta^2 - 1}$. First we consider the case $\eta = 0$ where the eigenvalue shows instability. We have two groups of spins with no intragroup interactions but for each pair, one from one group and one from the other, an interaction of the "x-y" model form [19]. Now we take the initial values of the spins in group #1 all to point in a direction a very small angle α from the the $\hat{z}$ axis, and the spins from group #2 to point exactly down. The question is: what is the time scale for spin mixing from the above mean field equations? Since the growth of the off-diagonal operator is as,

$$r_1 \sim e^{GNt}\,\alpha \tag{33}$$

The answer is $t_{\text{mix}} \approx (GN)^{-1} (\log\alpha)^{-1}$.

Next we ask what happens when $\alpha = 0$, where the mean field equations say there is no evolution at all. In ref.[19] we reported complete calculations based on (29) for cases of N=512 (and fewer) spins in each group. We found excellent fits to the form,

---

[2] Of course, the ν_e excess is very time dependent, decreasing rapidly during the duration of the neutrino burst.

$$t_{\rm ev} = \text{evolution time to 50\% mixed} = (GN)^{-1}\log N \quad (34)$$

a result that is backed up by unrigorous analytical work [20].

Thus although it is technically correct to say that this correction to the mean field approximation vanishes in the limit of a large number of particles, it is only by a logarithm, and logarithms are never huge. That said, the comparison of mean-field with an initial tilt α with the full $\alpha = 0$ solution shows that the initial-tilt produces more rapid transformations as long as $\alpha > N^{-1}$.

This is effectively the case in our present application. [3] Therefore in our present application we assume that the mean field assumptions are justified. We offer a caveat here, however; we have not carried out the real $2N$ spin solution when oscillations are present, where, for all we know, the outcome could be different than the mean field case. It is not guaranteed that the solution will interpolate in a simple way between the two limiting cases that we have analyzed.

We leave this problem for the future, but we can sharpen it a little here. Addressing the model of (29) in ref. [19], we also reported results for the case $\eta = 1$, where the eigenvalues λ are real. Here we found was no speed-up of the form (34). Instead we found, $t_{\rm ev} \sim G^{-1}N^{-1/2}$, slower by a factor of $\sqrt{N}/\log N$. This can be characterized as the perturbative time, since for small times, the transition probability for a particular spin is

$$\text{prob} \sim G^2 N t^2 \quad (35)$$

Thus our conjecture is that when the linear response calculation gives an exponentially growing mode, then the real solution gives speed-up as defined in (34). In contrast, when the eigenvalues, λ, are real, we get the perturbative rate.

More evidence for the latter is found in Friedland and Lunardini's analytic solution [21] of a model of the latter category (real eigenvalues for the perturbations in the mean field equations). Their model was basically that of (29) with $\eta = 1$ together with the assumption of isotropy, $[1 - \cos\theta_{\alpha,\beta}] \to 1$. [4]

6. DISCUSSION

We have made a case for rapid spectrum (and angle) mixing for systems that have two kinds of neutrinos and antineutrinos. We fully expect the case with all three flavors, and more mixing parameters, to mix rapidly in every direction; a primitive example was worked out in ref. [11].

To compare with other authors' results in related calculations, first we emphasize that most published examples of models with flavor exchange depend on MSW transitions over a distance in which the electron density is changing significantly. By contrast, our instabilities and rapid flavor exchange do not depend on changing the electron density and in any event can occur in regions with parameters that are far from resonance parameters, as in the region just under the neutrino-surface that we focused on here. The transition distances that we find in our calculations, of order 1 cm., are also much shorter than the resonance regions that appear at smaller electron densities.

The basic mechanism at work in our calculation is similar to that found in refs. [2]-[7] , which consider rapid flavor exchanges just downstream from the neutrino-surface. Though it is not so far from the region that we considered, the neutrino angular distributions are very different in the two regions. Outside of the neutrino surface all of the flow is outwards and the relative angles between neutrino trajectories are diminishing rapidly as one moves outwards. Since these angles are the key to all $\nu - \nu$ effects (as they are in our region as well) the results cannot be compared in detail with ours.

But we can compare general features of the results. The time scale for the rapid flavor exchanges found in refs. [6] and [5] is the "fast" rate as defined in our introduction, the geometric mean of the neutral current rate and the vacuum oscillation rate. As in our case the phenomenon does not depend on the space variation of the electron density. Except for the geometry, the physics appears to be the same as in our "six beam" example. We confirm the conclusions of ref. [6] as to the critical roles (and linking) of the ν_e excess and the normal vs. inverted hierarchy choice. In the case of normal hierarchy, the exchange occurs only for very small values of the electron excess. The case of inverted hierarchy allows considerable electron excess however.

Our results in sec.4, where we considered a less symmetrical angular distribution, are quite different. When the linearized stability analysis in the absence of neutrino mass terms shows a growing mode, then the solution for the complete problem shows large mixing for both the normal and inverted hierarchy cases, in the presence of moderate ν_e excess. The evolution rate is also an order of magnitude or more than in the more symmetric"six beam" example.

---

[3] We assume that the effective value of N would be the number of neutrinos in a volume of dimension of some neutrino coherence length, not that we know exactly how the latter should be defined.

[4] The same solution technique can be used to solve the case of $\eta = 1$ with two opposed beams that we discussed above, and also the complementary case of $\eta = 0$ and isotropy, in which case the mean field eigenvalues are $\lambda = \{0\,,\, z_1(0) + z_2(0)\}$, real for any initial configuration. The present remarks apply to the solutions of similar models in refs [22] as well.

Although the authors of ref. [5] did not find such behavior in the region that they treated, it is possible that if perfect cylindrical symmetry in the initial distributions were given up, then these super-fast turnovers would be produced for both the normal and inverted hierarchy.

We could ask how much it matters whether or not the emerging energy spectra are partially or fully homogenized. There is strong evidence in the literature [23]-[25] that it would matter significantly for the R process nucleosynthesis yields, though we believe that there is no single graph showing the effects with precision, as there is other complex physics involved. An interesting question is that of whether or not it matters to the actual explosion dynamics. The neutrino heating in the region above the neutrino-surfaces is augmented appreciably in a scenario in which ν_e's get boosted in average energy by trading spectra with ν_x's.

Of course, feeding our detailed considerations into a big code for the supernova is out of the question. The hydrodynamics plus neutrino transport problem has not been formulated in a way that admits collective effects of the kind we have discussed here, so far as we know; and there seems little possibility that it could be in a way that allowed whole-star computations in any reasonable reasonable amount of computer time.

But it would be easy for the numerical simulators to check the limiting case of our suggestion, total instantaneous flavor homogenization everywhere within the outer neutrino-surface, putting it by hand into the codes.

The third consequence, and most obvious observable consequence of our considerations, is the effect on the neutrino pulse signals from a nearby supernova. Much has been written on this subject, but the chance of observational data within the near future is very small, and loose ends can be cleared up after the fact, since the design of observing apparatus appears not to depend on the details of the predictions.
